

Evaluation of Tillage and Crop Rotation Effects in Certified Organic Production—McNay Trial, 2002

Dr. Kathleen Delate, assistant professor, Depts. of Horticulture & Agronomy
Dr. Cynthia Cambardella, soil scientist, USDA National Soil Tilth Lab
Jim Secor, farm superintendent, McNay Memorial Research Farm
Heather Friedrich, research associate, Dept. of Agronomy

Introduction

Organic farming has increased to an \$8 billion industry in the U.S. and continues to expand approximately 20% annually. In Iowa alone, organic acreage has increased from 13,000 in 1995 to 150,000 in 2000. Across the North Central region, there has been a great interest in planting organic soybeans on Conservation Reserve Program (CRP) land, where up to a 300% premium can be obtained compared to conventionally raised soybeans. Regulation of soil organic matter through additions of plant residues and proper crop rotations will determine the long-term sustainability of the system. The objectives of this research and education program included the following: (1) Establish plots dedicated to organic farming research on CRP land; (2) Implement production and management regimes for opening CRP land and for weed control in organic systems on CRP land; (3) Evaluate the biological and economic outcomes of the different systems; and (4) Promulgate technology transfer through demonstrations/Field Days and publications for area farmers and agricultural professionals.

Materials and Methods

This project involved the establishment of a long-term agroecological research (LTAR) site in southeast Iowa. The McNay Memorial Research Farm dedicated approximately two acres of a five-year old forage field (bromegrass and alfalfa) for this long-term project in Chariton, Iowa, in 1999. Bromegrass predominated in the field, as is typical of CRP land in this area of the state.

Experimental Design

Forty-eight plots (four tillage treatments, three crops and four replications), measuring 30 x 60 ft. each, were laid out in a randomized complete block design in September, 1999. The initial plowing of the CRP land, in the fall of 1999 and spring 2000, consisted of the following treatments: Treatment 1 = fall moldboard plowing; 2 = spring moldboard plowing; 3 = Kverneland® plowing (fall); and 4 = Howard Rotavator® (fall and spring). In 2000, a rotation of corn-soybean-oats underseeded with red clover was initiated to meet certified organic requirements. Each crop of the rotation was planted each year beginning in 2000.

Tillage and Mechanical Operations

Plots that were fall plowed in 1999 (Fall Moldboard and Kverneland®-plowed) were retained as fall plowed plots in 2000, 2001 and 2002. All fall tillage for the 2002 season was accomplished by November 30, 2001. Winter rye was broadcast on corn plots with a three-point mounted spreader on November 9, 2001, at a rate of one bushel per acre to serve as a ground cover to prevent erosion and mitigate weed populations in 2002 soybean plots. Spring plowing was completed on March 18, 2002, and the rye in soybean plots was disked on April 3. Manure was applied to all plots going to corn at a rate of 5,000 lb/acre on April 16, 2002. 'Blaze' oats and 'Prairie Fire' red clover were planted on April 13, 2002, at a rate of 2 bu/ac and 12 lb/ac, respectively. Soybeans (Pioneer 9305) were planted at a population of 175,000 plants/acre on

May 24. The corn variety Pioneer 34M94 was initially planted on May 10, at a rate of 31,000 plants/acre, but was replanted on June 7 due to a poor stand. Corn was rotary-hoed on June 18 and cultivated on June 25. Soybeans were rotary-hoed on June 7 then cultivated on June 18 and 25. Soybean plots were “walked” (large weeds removed by hand) on August 14, per local organic practices to remove any potentially staining weeds prior to harvest. Oats were harvested on July 18, 2002. Corn was harvested on October 16 and soybeans were harvested on October 11, 2002.

Sampling

Post-harvest soil samples (five random samples per plot) were taken on November 16, 2002, at depths of 0-4" and 4-8", using methods described by Cambardella (1994) for the Neely-Kinyon LTAR site. Sampling for soil, plant performance, weeds, insects and nematodes followed methods developed for the Neely-Kinyon LTAR site (Delate, 1999). Corn and soybean crop stand counts were taken on June 20 (14 and 27 DAP, respectively). Weed counts (3 square meter quadrats per plot) were taken on June 20 and July 18. Bean leaf beetles, which are associated with the soybean staining disease complex, were sampled in soybean plots on July 18, 2002, by sweeping 20 times per plot with a 15-inch diameter net. Corn borer populations were sampled by removing 3 randomly selected corn whorls per plot, and recording number of corn borer feeding holes and actual larvae on July 18. Soybean cyst nematodes were analyzed by sampling 5-6 inch soil cores per soybean plot for presence of eggs on September 24. Corn stalks were collected on September 24 for stalk nitrate analysis. Corn and soybeans were analyzed for protein, carbohydrates, fiber, and oil through the Iowa State University Grain Quality Laboratory in the Department of Food Science. A 250-gram sample of harvested soybeans was analyzed from each plot for percentage of stained soybeans (soybeans with a tan, brown or mottled appearance).

RESULTS AND DISCUSSION

Both corn and soybean plots yielded very well in 2002, although oat yields were impacted by lodging, due to winds and rain. There were no significant differences among the tillage treatments in corn plant populations (Fig.1) or in soybean stand counts (Fig. 2). Broadleaf and grass weed populations in corn and soybean plots were not significantly different on June 20 (Fig. 3 and 4) nor on July 18.

No significant yield differences were determined among treatments in oat, corn or soybean plots. Organic oats averaged 80 ± 5 bu/ac (Fig. 5). Corn yields averaged 186 ± 6 bu/acre with higher yields from plots that were fall-plowed (Fig. 6). Soybean yields ranged from 43.7 – 49.7 bu/acre (Fig.7).

No corn borers were detected on July 18. Bean leaf beetle populations were lower on July 18 than on September 10 (Fig. 8) and there were no differences in numbers of stained soybeans at harvest (Fig 9). There were no significant differences among treatments in corn or soybean grain quality in 2002 (Fig. 10 & 11). Corn stalk nitrate results were statistically similar, but corn stalks from fall plowed plots retained higher stalk nitrate than spring plowed plots (Fig. 12). Soybean cyst nematode eggs populations remained below the economic threshold (Fig.13). Overall, organic crop yields at the McNay LTAR site were among the highest yielding in the state.

ACKNOWLEDGEMENTS

We gratefully acknowledge the help of Noreen Wantate, Andrea McKern, Katie Schroeder and Jorge Alvaro; the ISU R&D farm staff (Jim Secor, Mark Honeyman, Dennis Shannon); the Howard Rotavator® Company and Pioneer Hi-Bred and Cal-West Seeds. The Clinton and Ottumwa NRCS office participated in the on-farm trial, approving our conservation plans once CRP land was tilled. We also involved staff at the USDA National Soil Tilth Lab. in soil analysis; Doug Karlen in fertilization recommendations; Mark Carlton, crop specialist; Jim Boes of Heartland Organic Marketing Cooperative in market information for organic soybeans; and the Iowa State University diagnostic laboratories in Agronomy, Horticulture, and the Grain Quality Initiative.
