

Comparison of Organic and Conventional Crops at the Neely-Kinyon Long-term Agroecological Research (LTAR) Site, 2015

Kathleen Delate, professor
Rebecca Johnson, research assistant
Departments of Horticulture and Agronomy
Randy Breach, ag specialist

Materials and Methods

The Neely-Kinyon LTAR site was established in 1998 to study the long-term effects of organic production in Iowa. Treatments at the LTAR site, replicated four times in a completely randomized design, include the following rotations: conventional Corn-Soybean (C-S), organic Corn-Soybean-Oats/Alfalfa (C-S-O/A), organic Corn-Soybean-Oats/Alfalfa-Alfalfa (C-S-O/A-A) and organic Corn-Soybean-Corn-Oats/Alfalfa (C-SB-C-O/A). Oat/alfalfa plots were field cultivated on April 11, 2015, and ‘Badger’ oats were underseeded with ‘BlueJay 3HR’ alfalfa at a rate of 90 lbs/acre and 15 lb/acre, respectively. Plots were cultipacked on April 11 after planting. Following harvest of the organic corn plots in 2014, winter rye was no-till drilled at a rate of 75 lb/acre on November 7, 2014.

Conventional corn plots were injected with 32% UAN on May 9, 2015, at 140 lb N/acre, disked on May 13 and June 9, and field cultivated on June 9. Chicken manure (S.W. Iowa Egg Cooperative, Massena, IA) was applied to organic corn plots at a rate of 6.9 tons/acre on April 11 in the organic C-S-O/A and C-S-O/A-A plots, and at a reduced rate of 2.9 tons/acre in the C-S-C-O/A plots on the same day. Corn and soybean variety selection and planting methods in 2015 were as follows: Blue River 56M30 corn was planted at a depth of 2.5 in. as untreated seed at a rate of 35,000 seeds/acre in the organic plots and as treated seed in conventional plots, on June 9, 2015.

Conventional soybean plots were disked on May 13 and June 8, and field cultivated on June 9. Blue River 24C3 soybeans were planted at a depth of 2 in. in organic and conventional plots at a rate of 175,000 seeds/acre on June 9, 2015. Conventional corn plots were sprayed on June 10, 2015, with Outlook™ at 20 oz/acre and Round-Up™ at 1 qt/acre; and Choice™ at 1 qt/100 gal on June 10. Conventional corn plots were cultivated on July 14 to deal with weed problems. Conventional soybeans received applications of Outlook™ at 20 oz/acre and Round-Up™ at 28 oz/acre; and Choice™ at 1 qt/100 gal on June 10. Conventional soybean plots were cultivated on July 14 to deal with weeds still emerging after herbicides.

The alfalfa and compost that was applied in the organic corn plots were plowed under on April 28, 2015. Plots were disked on May 9 and June 9, and field cultivated on June 9. Organic corn plots were rotary-hoed on June 22 and row-cultivated on June 29, which was two cultivations less than in 2013, due to wet weather.

Rye was disked in organic soybean plots on May 13 and June 8, and field cultivated on June 9, before soybean planting on June 9. Organic soybean plots that were not too wet were rotary hoed on June 19, and on June 22, and row-cultivated on June 29, July 8, and July 14. The length of time between planting and the first rotary hoeing (10 days) due to wet weather was damaging to weed management, so considerable time was invested in “walking” each organic soybean plot for large weeds above the canopy on August 9. There was a problem of weeds in conventional plots in 2015, even after repeated

herbicide applications, but these were not “walked” in keeping with the protocol of herbicide applications only in conventional plots.

Oat and alfalfa plots were sampled for nutrient analysis on May 18, 2015. Corn and soybean stands were counted on June 29, and weeds were counted within square meter quadrats at three randomly selected areas within a plot. Soil nitrate tests were conducted July 31, due to wet weather at the beginning of the season, by sampling at a 6–inch depth in three randomly selected areas in each plot in the corn row. Corn borer sampling was conducted on July 30 by sampling the whorl of three randomly selected corn plants per plot and counting incidence and numbers of corn borers. Corn stalk nitrate samples were collected on October 9. All crop and soil analyses were conducted at the Iowa State University Soil and Plant Analysis Laboratory, Ames, IA, and nematode analysis was conducted at the ISU Plant Disease Clinic (Ames, IA).

Alfalfa was baled on June 10, July 23, and September 14. Oat grain was harvested on July 20. Soybean plots were harvested on October 13 while corn plots were harvested on October 26. Grain samples were collected from each corn and soybean plot for grain quality analysis, which was conducted at the ISU Grain Quality Laboratory, Ames, IA.

Results and Discussion

The weather in 2015 was again extremely challenging, with a cool, wet May and 10 inches above normal rainfall in June. A very short window for planting was missed in May, pushing back planting dates to June. As a result of these extreme weather conditions and late planting, weed management and yields were affected in all plots. Oat and alfalfa stands were also affected by the poor weather, with N content in oat/alfalfa fields averaging

4.8% N and second-year alfalfa fields averaging 3.8% N (Table 1). Corn stands were similar between organic and conventional systems, averaging 34,110 plants/acre (Table 2). Organic soybean populations averaged 136,830 plants/acre, and conventional plots averaged 147,250 plants/acre, which was significantly higher than populations in the C-S-O/A-A plots (Table 3). Grass weed populations were highest in the organic corn plots, averaging 29 weeds/m², along with broadleaf weeds, which averaged 14 weeds/m², compared to 2 broadleaf weeds in conventional plots (Table 2). In the soybean plots, the organic plots averaged 31 grass weeds/m², compared to <1 weed/m² in conventional plots (Table 3). Broadleaf weeds were not significantly different between organic and conventional soybean plots because of high variability, but the organic plots averaged 20 weeds/m², compared to 5 weeds/m² in conventional plots. Weeds in organic fields could be attributed to wet fields in spring, which created poor conditions leading to a delay of 10 days between planting and the first rotary hoeing in corn and soybean plots. For good weed management in organic crops, the first rotary hoeing should occur within 2–3 days after planting.

Corn borers were again low in all fields, showing the high degree of tolerance or resistance in conventionally-bred (non-GMO) corn varieties. No corn borer damage was detected in any plants sampled in all corn plots (Table 4). Although there was no statistical difference between soil nitrate levels, conventional corn plots averaged 3.1 ppm NO₃-N, while organic soils averaged 2.6 ppm NO₃-N (Table 5), far below the recommended level of 25 ppm in all plots.

Several plots were re-planted on June 29 due to poor stands in wet fields, so silage samples were collected on September 16 to decide if corn should be chopped or left for grain

harvest in these plots. Chopped corn biomass would have averaged 12,098 lb/acre, which is a very good silage yield (Table 6). Nutrient analysis of the chopped corn averaged 42% carbon and 2.3% N (Table 7). Corn stalk nitrate levels averaged 1,004 ppm nitrate-N in conventional corn, and 2,398 ppm nitrate-N in the organic corn, with no statistical differences between systems (Table 8).

Soybean cyst nematode populations were low and similar between organic and conventional plots where the organic plots averaged 119 eggs per 100 cc of soil, compared to 100 eggs per 100 cc in the conventional plots (Table 9).

Oat yields were impacted by wet weather. There was no difference in oat yield between the three- and four-year rotations, averaging 75 bu/acre (Table 10). We expected alfalfa growth to be impacted by the wet spring, but yields averaged 4.7 tons/acre, which was significantly higher than the 1.8 tons/acre yield of 2013, and similar to the 4.6 tons/acre yields in 2014 and 2015. Oat and alfalfa baleage in the O/A plots averaged 1.47 tons/acre.

Organic corn yields in the fields planted on June 9 averaged 109 bu/acre compared to conventional yields of 126 bu/acre (Table 11), with no statistical differences between systems. The combination of late planting, and excessive rains, which rapidly mineralized N from both synthetic fertilizer and compost, impacted yields in all plots, as demonstrated by the lack of soil N in July (Table 5). The numerically highest organic yield was in the C-S-O/A rotation, at 115 bu/acre. Yields in the June 29 re-planted corn plots averaged 74 bu/acre, which, based on November 25, 2015, organic prices, would have been worth \$740/acre, compared to \$271/acre for conventional corn. Despite insufficient mechanical weed management in organic soybean plots due to weather impacting field

operations, the subsequent high weed populations in the organic soybeans were managed through manual removal (“walking”) and yields were remarkably high, averaging 54 bu/acre in both organic and conventional systems which received multiple herbicides (Table 12).

Corn grain quality remained acceptable for organic feed markets despite the extreme weather. Protein levels were higher in conventional corn, at 8.3%, compared to 7.7% in organic corn (Table 13). Corn density was equivalent between systems, at 1.25%. Moisture was high, averaging 20% in organic corn at harvest, and also in the conventional corn (18.5%). Corn starch was equivalent in both systems, averaging 72%. Corn oil content was similar, at 4.2%, in both systems.

Soybean moisture levels were not different between systems, averaging 9.7% in organic soybeans and 9.5% in conventional soybeans (Table 14). Protein levels were equivalent between systems overall at 37%, but the C-S-O/A rotation had greater protein content than the conventional soybeans. Soybean carbohydrate levels averaged 22%, with only small differences between systems (e.g., conventional soybeans averaged 22% compared to 21.5% in C-S-O/A soybeans). Oil levels (18%) were also similar across all rotations.

LTAR 2015 Soil Data Summary

USDA-ARS (C. Cambardella) sampled LTAR plot by collecting five randomly-located soil cores (0-15 cm) from each plot in the fall after harvest but before any field operations (cover crop planting) in 2015. The cores were mixed together to produce one composite sample from each plot. Soil quality was higher in the organic rotations relative to the conventionally managed corn-soybean rotation in the fall of 2015. The organic soils had more microbial biomass C and N, higher P, K, Mg and Ca

concentrations, and lower soil acidity than conventional soils (Table 15). The long-term 4-yr organic rotation had more microbial biomass C and stable macroaggregates than the 3-yr organic rotation in the fall of 2015, although the effect was not statistically significant for macroaggregates. The results suggest that the extra year of alfalfa increased the resilience of the 4-yr organic rotation through increased microbial biomass and more stable soil structure.

Acknowledgments

We would like to thank the Leopold Center for Sustainable Agriculture for their support of the Neely-Kinyon LTAR site. We also thank the Wallace Foundation for their input and support. Thanks also go to Bernie Havlovic, Bob Turnbull, Rachel Tan, Brody Erlandson, Knyli Erlandson, Meaghan Daley, and Rebecca Johnson, for their help in production, data collection and analytical aspects of this project. We also thank Adair County Extension and Outreach office, Charles Hurburgh and Glen Rippke of the ISU Grain Quality Lab, Kerry Culp of the ISU Soil and Plant Analysis Lab, and Blue River Hybrids for their support.
